Driven by the need to understand the ecological factors involved in the emergence of betacoronavirus (the genus causing the SARS and MERS disease in human) through bat hosts, we develop an approach to the assessment of spillover risk based on the Geographic Mosaic Theory of Coevolution. In doing so, we provide a global mapping of the spillover risk posed by betacoronaviruses, reflecting the fact that this risk has many ecological and evolutionary origins. Our framework reveals that reservoir richness alone, although a component of viral hazard, is not a sufficiently integrative predictor of risk. We offer alternative insights based on viral sharing, host compositional uniqueness, and host phylogenetic diversity. By comparing our aggregated measure of risk to a proxy for human density, namely the proportion of each pixel that is covered by urban or built land, we provide a synthetic risk map, allowing the identification of hotspots where the bat-betacoronavirus system may originate novel viruses in humans.

1 Spillover risk is multidimensional and complicated. Within a pool of competent hosts, it is driven by a
2 multiplicity of factors (Plowright et al. 2017). Although proxies for the local richness of hosts is commonly
3 analysed (see e.g. Anthony et al. 2017 for coronaviruses), there is an argument to be made that species
4 who are not (known as) competent hosts of a specific virus genus may not factor into this (Plowright et al.
5 2015), calling for species-level information. This is especially true as competence data increases predictive
6 power when the taxonomic scope of hosts of a viral family increases (Becker et al. 2020, Mull et al. 2022).
7 Similarly, host species who share viruses at different rates should be weighted accordingly (Albery et al.
8 2020). In mammals, key functional traits (for which phylogeny is a reasonable proxy) are determinants of
9 the spillover potential (Olival et al. 2017); these include, notably, body mass, and affinity for urban
10 environments (Albery et al. 2022). Finally, especially when the pool of potential hosts spans the entire
11 globe, there may be local host pools that are highly unique; not having been observed in other locations,
12 these can act on the overall risk either by providing novel contact opportunities, reflecting unique
13 host-environment combinations (Engering et al. 2013), or facilitating rapid evolutionary changes in
14 specialism of their pathogens (Agosta et al. 2010). In the specific case of generalist pathogens (which is
15 the case many viruses in the betacoronavirus genus, see e.g. MacLean et al. 2021), there is conceptual and
16 empirical support to the idea that these community-level mechanisms are even more important in driving
17 the overall risk (Power and Mitchell 2004).

18 In this paper, we examine the biogeographic structure of bats-betacoronaviruses associations, based on a
19 curated dataset of all confirmed bat hosts of betacoronaviruses. By drawing on concepts from the
20 Geographic Mosaic Theory of Coevolution (GMTC; Thompson 2005), we turn these associations into a
21 spatially explicit additive mapping of zoonotic risk components, revealing the extreme heterogeneity of
22 risk at the global scale. Explicitely framing the notion of spillover risk based on propositions from the
23 GMTC (which is to say, based on a framework linking interactions between species to change within
24 species) is a novel idea, that should be relatively general. Indeed, it only assumes the action of well
25 described evolutionary mechanisms. The benefit of this approach is to provide the potential for a more
26 dynamic and nuanced understanding of risk: not only on ecological timescales, but also by providing
27 clues about which areas can change over micro-evolutionary timescales. This provides a way to look at
28 spatial structure by accounting for more notions than species richness/similarity, but also a way to identify
29 spatial areas of higher risk.

30 We identify the Amazon and South-Eastern Asia as hotspots where the phylogenetic distinctiveness of

31 betacoronaviruses is the highest (Anthony et al. 2017); surprisingly, current data suggest that viral sharing
32 between hosts is high in the Amazon and low in South-Eastern Asia, which has the potential to result in
33 different evolutionary dynamics between these two regions, hinting at different futures for their viral
34 communities. This work is important both as a description of the bats-betacoronavirus complex, but also
35 because more broadly, bats are known reservoirs for a variety of emerging viruses and other pathogens
36 (Calisher et al. 2006, Melaun et al. 2014), making balancing the needs for bat conservation and disease
37 prevention most likely very difficult and a source of human-wildlife conflicts, especially in more densely
38 populated areas (Stone et al. 2015, Rego et al. 2015).

39 Methods

40 Known betacoronavirus hosts

41 We downloaded the data on bats hosts of betacoronaviruses assembled by Becker et al. (2022) from
42 <https://www.viralemergence.org/betacov> on Apr. 2022, and filtered it to “known” hosts (established
43 before the emergence of SARS-CoV-2) and “novel” hosts (confirmed through sampling since the
44 emergence of SARS-CoV-2). The original database was assembled by a combination of data mining and
45 literature surveys, including automated alerts on the “bats” and “coronavirus” keywords to identify novel
46 empirical evidence of bats-betacoronaviruses associations.

47 Bats occurrences

48 We downloaded the rangemap of every extant bat species that was either classified as an empirically
49 documented host of beta-coronaviruses from the previous step, according to recent IUCN data (IUCN
50 2021). The range maps were subsequently rasterized using the rasterize function from GDAL (Rouault et
51 al. 2022) at a resolution of approximately **TK TP**. For every pixel in the resulting raster where at least one
52 bat host of betacoronavirus was present, we extract the species pool (list of all bat species), which was used
53 to calculate the following risk assessment components: phylogenetic diversity, bat compositional
54 uniqueness, and predicted viral sharing risk.

55 **Bats phyogeography**

56 For every pixel, we measured Faith's Phylogenetic Diversity (Faith 1992) based on a recent synthetic tree
57 with robust time calibration, covering about 6000 mammalian species (Upham et al. 2019). Faith's PD
58 measures the sum of unique branches from an arbitrary root to a set of tips, and comparatively larger
59 values indicate a more phylogenetic diverse species pool. We measured phylogenetic diversity starting
60 from the root of the entire tree (and not from Chiroptera); this bears no consequences on the resulting
61 values, since all branches leading up to Chiroptera are only counted one per species pool, and (as we
62 explain when describing the assembly of the composite risk map), all individual risk components are
63 ranged in [0,1]. This measure incorporates a richness component, which we chose not to correct for; the
64 interpretation of the phylogenetic diversity is therefore a weighted species richness, that accounts for
65 phylogenetic over/under-dispersal in some places.

66 **Bats compositional uniqueness**

67 For every species pool, we measured its Local Contribution to Beta-Diversity (Legendre and De Cáceres
68 2013); LCBD works from a species-data matrix (traditionally noted as \mathbf{Y}), where species are rows and sites
69 are columns, and a value of 1 indicates occurrence. We extracted the \mathbf{Y} matrix assuming that every pixel
70 represents a unique location, and following best practices (Legendre and Condit 2019) transformed it
71 using Hellinger's distance to account for unequal bat richness at different pixels. The correction of raw
72 community data is particularly important for two reasons: first, it prevents the artifact of richer sites
73 having higher importance; second, it removes the effect of overall species richness, which is already
74 incorporated in the phylogenetic diversity component. High values of LCBD indicate that the pixel has a
75 community that is on average more dissimilar in species composition than what is expected knowing the
76 entire matrix, i.e. a more unique community. Recent results by Dansereau et al. (2022) shows that LCBD
77 measures are robust with regards to spatial scale, and are therefore applicable at the global scale.

78 **Viral sharing between hosts**

79 For all bat hosts of betacoronaviruses, we extracted their predicted viral sharing network (Albery et al.
80 2020). This network stores pairwise values of viral community similarity. To project viral sharing values

81 into a single value for every pixel, we averaged the pairwise scores. High values of the average sharing
82 propensity means that this specific extant bat assemblage is likely to be proficient at exchanging viruses.

83 **Composite risk map**

84 To visualize the aggregated risk at the global scale, we combine the three individual risk components
85 (phylogenetic diversity, compositional uniqueness, and viral sharing) using an additive color model
86 (Seekell et al. 2018). In this approach, every risk component gets assigned a component in the RGB color
87 model (phylogenetic diversity is green, compositional uniqueness is red, and viral sharing is blue). In
88 order to achieve a valid RGB measure, all components are re-scaled to the [0,1] interval, so that a pixel
89 with no sharing, no phylogenetic diversity, and no compositional uniqueness is black, and a pixel with
90 maximal values for each is white. This additive model conveys both the intensity of the overall risk, but
91 also the nature of the risk as colors diverge towards combinations of values for three risk components. Out
92 of the possible combinations, the most risky in terms of rapid diversification and spillover potential is high
93 phylogenetic diversity and low viral sharing (Gomulkiewicz et al. 2000, Cavender-Bares et al. 2009), in
94 that this allows multiple independent host-virus coevolutionary dynamics to take place in the same
95 location. In the colorimetric space, this corresponds to yellow – because the HSV space is more amenable
96 to calculations for feature extraction (see e.g. Keke et al. 2010), we measured the risk level by calculating
97 the angular distance of the hue of each pixel to a reference value of 60, and weighted this risk level by the
98 value component. Specifically, given a pixel with colorimetric coordinates (h, s, v) , its ranged weighted
99 risk value is

$$v \times \left[1 - \frac{|\text{atan}(\cos(\text{rad}(h)), \sin(\text{rad}(h))) - X|}{2\pi} \right],$$

100 where X is $\text{atan}(\cos(\text{rad}(60)), \sin(\text{rad}(60)))$, a constant approximately equal to 0.5235.

101 **Viral phyogeography and evolutionary diversification**

102 We used the following query to pull all betacoronavirus sequence data from the GenBank Nucleotide
103 database except SARS-CoV-2; (“Betacoronavirus”[Organism] OR betacoronavirus[All Fields]) NOT
104 (“Severe acute respiratory syndrome coronavirus 2”[Organism] OR sars-cov-2[All Fields]). We added a

105 single representative sequence for SARS-CoV-2 and manually curated to remove sequences without the
106 RNA-dependent RNA polymerase (RdRp) sequence or that contained words indicating recombinant or
107 laboratory strains including “patent,” “mutant,” “GFP,” and “recombinant.” We filtered over-represented
108 taxa including betacoronavirus 1, hCoV-OC43, Middle East respiratory syndrome coronavirus, Murine
109 hepatitis virus, and hCoV-HKU1. Curated betacoronavirus RdRp sequences were then aligned using
110 MAFFT v 1.4.0 (**Katoh and Standley 2013**, parameters in text?) and a maximum likelihood tree
111 reconstructed in IQ-TREE v 1.6.12 (Nguyen et al. 2015) with ModelFinder (Kalyaanamoorthy et al. 2017)
112 ultrafast bootstrap approximation (Hoang et al. 2018) and the following parameters (**STEPH WILL ADD,**
113 **parameters in text?**).

114 We first tested the hypothesis that hotspots of viral diversification would track hotspots of bat
115 diversification. To do so, we plotted the number of known bat hosts (specifically only those included in the
116 phylogeny, so there was a 1:1 correspondence between data sources) against the “mean evolutionary
117 distinctiveness” of the associated viruses. To calculate this, we derived the fair proportions evolutionary
118 distinctiveness (Isaac et al. 2007) for each of the viruses in the tree, then averaged these at the bat species
119 level, projected these values onto their geographic distributions, and averaged across every bat found in a
120 given pixel. As such, this can be thought of as a map of the mean evolutionary distinctiveness of the
121 known viral community believed to be associated with a particular subset of bats present.

122 **Co-distribution of hosts and viral hotspots**

123 Subsequently, we tested the hypothesis that the biogeography of bat betacoronaviruses should track the
124 biogeography of their hosts. To test this idea, we loosely adapted a method from (Kreft and Jetz 2007,
125 2010), who proposed a phylogenetic method for the delineation of animal biogeographic regions. In their
126 original method, a distance matrix - where each row or column represents a geographic raster’s grid cell,
127 and the dissimilarity values are the “beta diversity similarity” of their community assemble - undergoes
128 non-metric multidimensional scaling (NMDS); the first two axes of the NMDS are projected
129 geographically using a four-color bivariate map. Here, we build on this idea with an entirely novel
130 methodology. First, we measure the phylogenetic distance between the different viruses in the
131 betacoronavirus tree by using the cophenetic function in ape (Paradis and Schliep 2019); subsequently, we
132 take a principal components analysis of that distance matrix (readily interchangeable for NMDS in this
133 case) to project the viral tree into an n-dimensional space. We then take the first two principal

134 components and, as with the evolutionary distinctiveness analysis, aggregated these to a mean host value
135 and projected them using a four-color bivariate map.

136 Results and discussion

137 Host richness does not predict virus distinctiveness

138 Bats are found worldwide and are both one of the most diverse groups among mammals (**Moratelli &**
139 **Calisher, 2015**), and one of the main animal reservoir for different strains of betacoronaviruses (Drexler et
140 al. 2014). This has attracted attention to areas where high diversity of bats, and therefore presumably high
141 diversity of betacoronaviruses, can be an important issue for human health (Calisher et al. 2006, Moratelli
142 and Calisher 2015). By overlaying the IUCN rangempas for confirmed bat hosts of betacoronaviruses
143 [fig. 1; top], we see that the the main hotspots of host richness are primarily South-Eastern Asia, parts of
144 Southern Europe, and to a lesser extent parts of Africa in the -25-0 range of latitudes. The description of
145 host richness is an important first step towards understanding risk, as previous research (Anthony et al.
146 2017, Mollentze and Streicker 2020) states that locally diverse bat communities could maintain more
147 viruses and hence, a higher probability of having a pathogen that could represent a risk for human health.

148 [Figure 1 about here.]

149 Nevertheless, locally diverse and virus-rich bat communities could represent an increased risk of spillover
150 under climate change through the creation of novel interactions (Carlson et al. 2022), and therefore the
151 diversity of betacoronavirus strains should similarly be ccounted for. In fig. 1 (bottom), we contrast the
152 evolutionary distinctiveness of bats and viruses – this reveals a slightly different portrait than bat richness
153 alone. Chiropterans can be classified, from a macro-evolutionary standpoint, as microchiroptera and
154 macrochiroptera, where macrochiroptera have an older history from an evolutionary perspective
155 compared to macrochiroptera (Teeling et al. 2005, Springer 2013). Specifically, we would expect that the
156 so-called “New World” group of bats, being more evolutionary distinct, would also have evolutionary
157 distinct viruses. Indeed fig. 1 (bottom) reveals it to be the case, and this region harbors a distinct
158 bat-betacoronavirus complex. By contrast, South-Eastern Asia has a lot of non-evolutionary distinct bats,
159 but evolutionary-distinct viruses.

160 It is noteworthy that outside of South America, viral evolutionary distinctiveness does not accurately
161 tracks host diversity, with some areas having over-distinct viruses (southern China but, oddly, not the rest
162 of southeast Asia). There are a number of likely explanations. First, given the richness of bats in southeast
163 Asia, many betacoronaviruses likely remain to be discovered in this region. Indeed, global predictions by
164 Becker et al. (2022) highlight that southeast Asia is a likely hotspot of unconfirmed hosts of
165 betacoronaviruses, which would likely result in additional viral discoveries. This idea is unsurprising given
166 the growing realization, around the emergence of SARS-CoV-2, that a unique lineage of similar viruses are
167 widespread in bats but still mostly undescribed. The most distinct bats/betacoronavirus complex is found
168 in South America, a region with a comparatively lower number of hosts; this matches with the isolation
169 through variance of the host group, and may highlight a different co-evolutionary dynamic. Alternatively,
170 this distinctiveness hotspot may be a product of under-sampling: South-America is one of the places
171 where the fewest betacoronaviruses have been discovered (Anthony et al. 2017, Olival et al. 2017, Allen et
172 al. 2017), resulting in sparser phylogenetic tree, thereby artificially inflating distinctiveness. Adding more
173 viruses would bring the distinctiveness of known sequences down.

174 **The phylogeographic regions of hosts and their viruses overlap**

175 Despite the difference in evolutionary distinctiveness globally, there are reasons to expect that the
176 phylogeography of bats and betacoronaviruses should show some degree of congruence. High density of
177 hosts sharing the same virus (albeit possibly different strains) can drive or result from evolution of the bat
178 antiviral immune system, resulting in spatially distinct immunological responses, as evidenced in several
179 bat species (Banerjee et al. 2020). Immune characteristics that allow bats to be better adapted to infection
180 by emerging viruses (Gorbunova et al. 2020, Irving et al. 2021), in addition to being hardcoded in their
181 genome (Jebb et al. 2020), may be related to a wide variety of diets (Banerjee et al. 2020, Moreno Santillán
182 et al. 2021, Muylaert et al. 2021), themselves likely to be driven by spatial effects, especially at the local
183 scale – bats, indeed, occupy a variety of environments, and therefore display a variety of adaptations to
184 these environments.

185 [Figure 2 about here.]

186 In fig. 2, we show a projection of the phylogeographic signal of bats (top) and viruses (bottom) in space;
187 the distinct groupings (represented by different colors symbolizing positions in the subspace formed by

188 the first two axes of the PCoA) are essentially equivalent between the two groups, and can be coarsely
189 delineated as southeast Asia, Eurasia above a northing of 25, and Africa and south America. These results
190 suggest that, although the evolutionary distinctiveness of the bat/betacoronavirus complex varies spatially,
191 the system shows an important degree of spatial consistency, with a reduced number of bioregions.
192 Available information describing the spillover of zoonotic betacoronaviruses of bat origin where data was
193 available before and up through the COVID-19 pandemic puts spillover events of SARS-CoV-2 in Wuhan,
194 China; SARS-CoV in Guangdong, China based on the presence of closest known viruses circulating in
195 nature, and a nearby location where serological (antibody) evidence has indicated human exposure to
196 SARS-like viruses (Wang et al. 2018); MERS-CoV in Saudi Arabia based on index cases available from a
197 recently-published compendium of cases (Ramshaw et al. 2019). For the latest event, most if not all index
198 cases are presumed to be camel-to-human transmission, and the precise origin point (if it exists) of
199 MERS-CoV in bats is uncertain. Recent recombinant canine coronavirus spillover events in Haiti
200 (Lednicky et al. 2021) and Europe (Vlasova et al. 2022) are not relevant here, as bats' involvement in these
201 cycles of transmission have been supposed to be non-existent. These index cases fall within different
202 phylogeographic bioregions (fig. 2), which further highlight the issue that different host-virus sub-systems
203 may lead to widespread emergence.

204 **Coevolution-informed spillover risk is different in space**

205 As host richness, joint distinctiveness, or phylogeographic structure suggest that the bat/betacoronavirus
206 complex is globally fragmented enough to give rise to both different levels of risk (as evidenced by the
207 spatial location of spillover events) and different types of co-evolutionary dynamics, we turn to the
208 Geographic Mosaic Theory of Coevolution (Thompson 2005) to provide a measure of risk accounting for
209 multiple processes. In fig. 3, we overlapped three components of spillover risk: viral sharing, *i.e.* the
210 chance that two bats will share viruses overall; Local Contribution to Beta Diversity, *i.e.* the fact that a bat
211 community is compositionally unique compared to the average compositional similarity across the entire
212 system; finally, host phylogenetic diversity, *i.e.* how dispersed the bats in a location are within the tree of
213 life. This approach leads to the definition of broad biogeographic regions of risk, where the same color
214 represents the same type of risk. By way of contrast to figures fig. 1 and fig. 2, these regions do not
215 necessarily overlap with previous spatial partitions of the bat/betacoronavirus complex.

[Figure 3 about here.]

217 From the perspective of spillover risk, the most important combination of factors is a high phylogenetic
218 diversity of hosts with low viral sharing; this, essentially, means that very different betacoronavirus could
219 co-exist within the same place. This is particularly the case given that betacoronaviruses often evolve and
220 even achieve host shifts through recombination, which requires the co-occurrence of sufficiently distinct
221 viruses to be a major driver of emergence. In fig. 3, this corresponds to yellow to pale green areas, which
222 are essentially limited to South-Eastern Asia, and to some part of Sub-Saharan Africa. Adopting a
223 geographic mosaic theory perspective on risk, other regions of the world are of lesser concern fig. 4. Our
224 risk decomposition does not account for viral diversity or distinctiveness. The simple rationale behind it is
225 that the acquisition of viral data is rarely disconnected from the acquisition of host data; furthermore, there
226 are more sources of information on hosts than on viruses, allowing to develop a host-centric perspective
227 on risk. Areas with high bat diversity and high turnover *may* facilitate the evolutionary radiation of
228 viruses, matching previous findings that the diversification of bat coronaviruses is driven largely by host
229 shifts (inter-genus or higher levels of cross-species transmission) and, to a lesser degree, cospeciation and
230 sharing (intra-genus cross-species transmission; Anthony et al. 2017). This diversification is not an actual
231 risk factor for spillover itself, but acts downstream of a spillover event by increasing the random chance of
232 the emergence of a virus with the raw genomic components required for the potential to infect humans.

[Figure 4 about here.]

234 From another perspective, areas of high host uniqueness and virus sharing (red-to-pink) could provide
235 hotspots of betacoronavirus risk through mixing of unique viruses (via codivergence) and in turn
236 recombination. Under our framework, such a hotspot was identified in Madagascar, where most bat
237 species are endemic following evolutionary divergence from sister species in both African and Asian
238 continents (e.g. Shi et al. 2014). Recent surveillance (Kettenburg et al. 2022) has identified a novel
239 betacoronavirus (in the subgenus *Nobecovirus*) in Madagascar-endemic pteropid bat species (*Pteropus*
240 *rufus*, *Rousettus madagascariensis*), emphasizing strong proof of principle in model predictions.

241 **Human occupancy drives different levels of effective risk globally**

242 Based on the previous result, we extracted the risk component from the composite map (see Methods), to
243 provide a single measure of risk varying between 0 and 1. This measure is presented in fig. 4. However,
244 this maps the potential risk, which must be weighed by the potential for contacts with humans. As a proxy
245 for this measure, we used the proportion of build/urban land from the EarthEnv dataset: this is a
246 reasonable proxy for the density of humans per unit area, which increases the probability of pathogen
247 spread more widely (Hazarie et al. 2021). Since human activity is required to amplify the frequency of
248 virus encounters and thus create areas of viral amplification, mapping the potential risk against measures
249 of land use is required to generate a more actionable assessment of risk. This map is presented in fig. 5.
250 Most of South America and Europe are at low risk, as although densely populated, settlements tend to be
251 in areas with lower potential risk. However, this mapping reveals that South-East Asia, the Indian
252 subcontinent, and parts of sub-Saharan Africa, are at high risk due to the overlap between built areas and
253 bat communities representing more opportunities for cross-species transmission of betacoronaviruses. In
254 looking for the origins of SARS in China, Xu et al. (2004) present serological evidence that strongest
255 human-animal contact results in higher risk of virus exposure, regardless of the animal species, but that
256 different types of contact had different impacts. Ideally, finer-grained information about human activity
257 (rather than human presence through anthropisation) could allow to partition this risk further.

258 [Figure 5 about here.]

259 **Conclusion**

260 Our study focuses largely on the biogeography of hosts. Yet, we know that viruses with high host
261 plasticity, that is, the ability of a given virus to adapt to various taxonomic orders and ecological groups
262 (Kreuder Johnson et al. 2015), are more likely to amplify viral spillover, followed by secondary
263 human-to-human transmission, and geographical spread (Hazarie et al. 2021). High viral host plasticity is
264 an especially important trait for RNA viruses like betacoronaviruses (Haddad et al. 2021). Indeed, our
265 analysis of viral sequences reveals that Latin America is a hotspot of viral distinctiveness, suggesting that
266 this part of the bats-betacoronavirus system may be undergoing independent evolutionary dynamics
267 (related species sharing viruses that are different from the rest of the global pool). The other hotspot of

268 viral distinctiveness is S.E. Asia, in which richness is high but sharing is low; this suggests a different type
269 of evolutionary dynamics (unrelated viruses coevolving with evolutionarily distinct hosts, generating high
270 diversity locally). Both of these areas should be priority areas for sampling, especially since Becker et al.
271 (2022) advance that they harbor undiscovered hosts of beta-coronaviruses. This diversity of hosts, and the
272 mechanisms by which the exchange of viruses occurs between species, is largely affected by the local
273 environmental conditions and environmental change.

274 Bats are important reservoir hosts for different classes of microorganisms, many of which a threat to
275 human health (Letko et al. 2020, Van Brussel and Holmes 2022). Chiropterans emerged around 64 million
276 years ago and are one of the most diverse mammalian orders, with an estimated richness of more than
277 1400 species (Peixoto et al. 2018, Simmons and Cirranello 2020). They exhibit a broad variety of habitat
278 use, behaviour, and feeding strategies, putting them at key positions in the delivery and provisioning of
279 several ecosystem services, tied to important ecosystem-derived benefits to human (Kasso and
280 Balakrishnan 2013). For example, bats are an essential component of many seed-dispersal networks
281 (Mello et al. 2011). Over two-thirds of bats are know to be either obligate or facultative insectivores,
282 therefore playing an important role in the regulation of insect pests that can affect crops (Williams-Guillén
283 et al. 2008, Voigt and Kingston 2016), and vectors of pathogens that put a risk on human health
284 (Gonsalves et al. 2013a, b). Because bats are globally distributed and have a long evolutionary history,
285 phylogeographic and biogeographic approaches are required to shed light on the contemporary
286 distribution of coevolutionary processes between bats and the pathogens they host. Not all areas in which
287 bats, viruses, and human are co-occurring are facing a risk of spillover towards human populations, and
288 the areas in which this risk exist may not be facing risks of the same nature and magnitude.

289 There are several factors that drive changes in the diversity of bats (Alves et al. 2018), but human
290 activities' effects on the ecosystem (like modifications of land use) could significantly decrease it.
291 Therefore, it can be suggested that changes in the diversity of betacovs in bats are linked to their
292 biogeographic variation, and human population density and other anthropogenic factors are decisive
293 moderators for its implications in public health. With the increase of contact between humans and
294 potential hosts, we also increase the risk of emergence of novel diseases (Johnson et al. 2020), as previous
295 studies on RNA viruses suggest the importance of host phylogeography at the time of virus dispersal
296 (Gryseels et al. 2017). One of these scenarios where interaction between bats and humans can occur can
297 be seed dispersal in tropical agroecosystems. It opens the discussion of whether the fruits thrown by bats

298 not only disperse seeds but could also be a source of indirect interaction between viruses of bat origin and
299 humans (Deshpande et al. 2022). This represents a challenge for conservation strategies and disease
300 ecology since some areas can have both potential for the acquisition of zoonotic viruses and bat-human
301 interactions; in particular, the challenge lies in the fact that actual exposure must then be quantified
302 accounting for several transmission scenarios, including both direct and indirect bat - human interaction.

303 **Acknowledgements:** We acknowledge that this study was conducted on land within the traditional
304 unceded territory of the Saint Lawrence Iroquoian, Anishinabewaki, Mohawk, Huron-Wendat, and
305 Omàmiwininiwak nations. This work was supported by funding to the Viral Emergence Research
306 Initiative (VERENA) consortium including NSF BII 2021909 and a grant from Institut de Valorisation des
307 Données (IVADO). This research was enabled in part by support provided by Calcul Québec
308 (www.calculquebec.ca) and Compute Canada (www.computecanada.ca). NF is funded by the NSERC
309 BIOS² CREATE program. TP and NF are funded by the Courtois Foundation. RLM was supported by
310 Bryce Carmine and Anne Carmine (née Percival), through the Massey University Foundation.

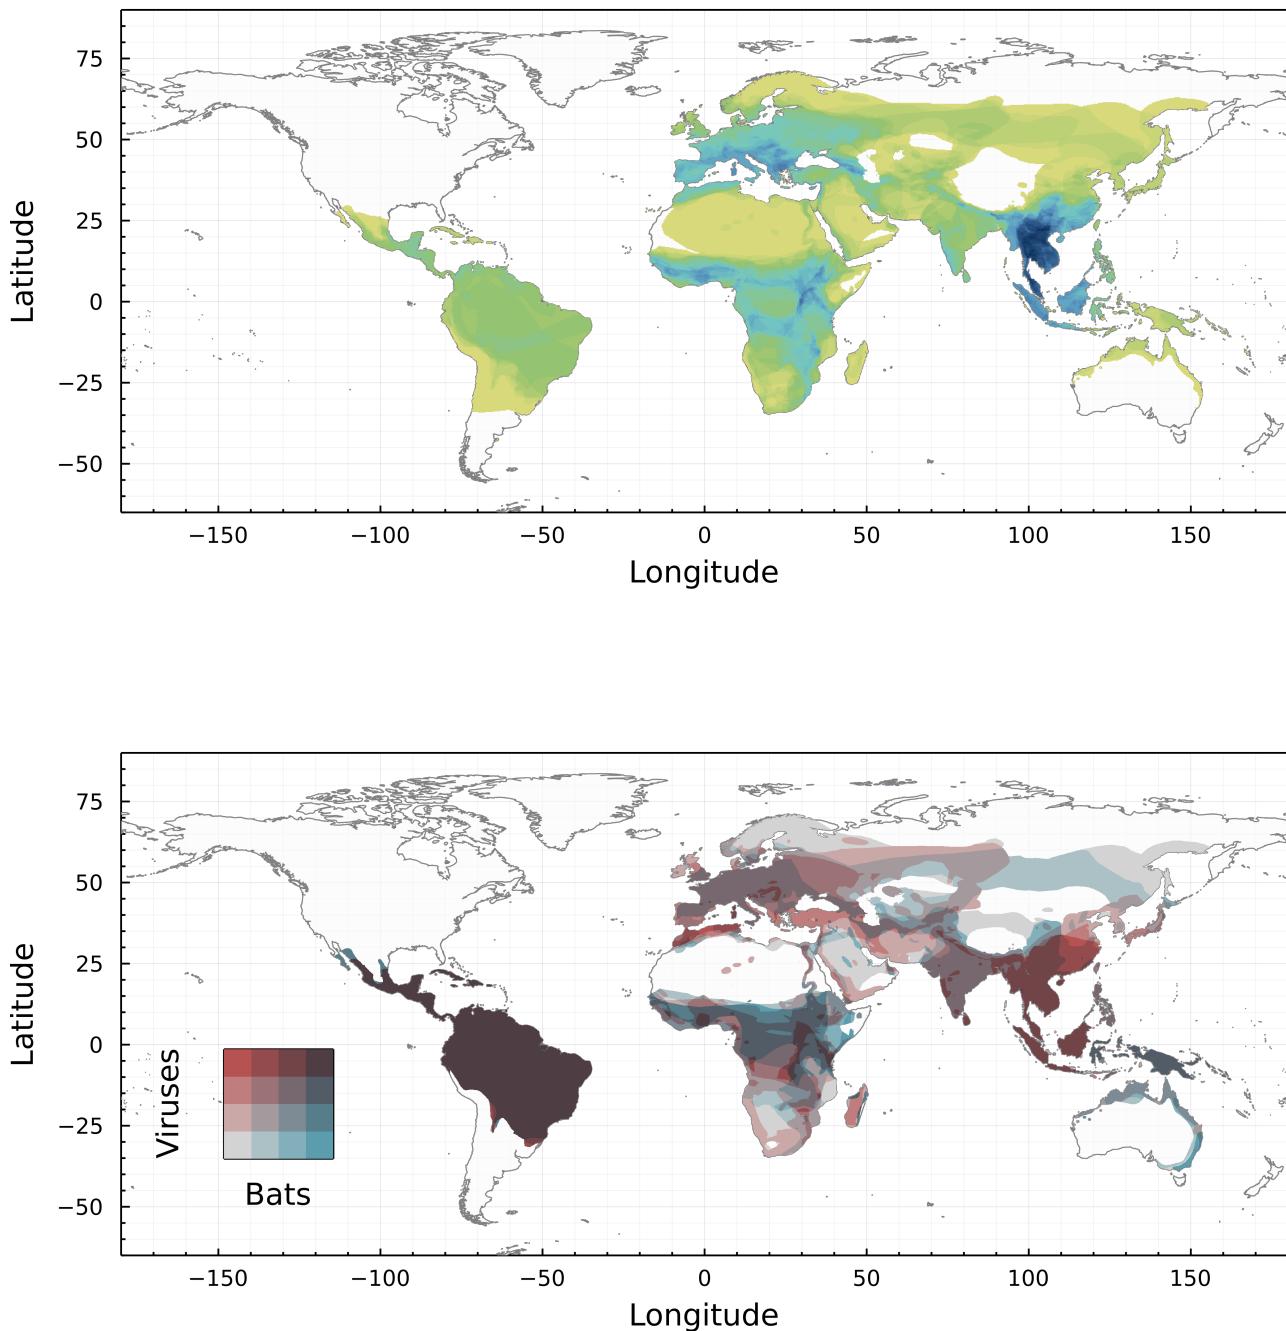

Figure 1: Top panel: relative diversity of known bat hosts of betacoronaviruses. This map shows that the region with the largest number of possible hosts is South-Eastern Asia. Bottom panel: congruence between the evolutionary distinctiveness of the hosts (grey to blue) and the viruses (grey to red). By contrast to the richness map, this reveals that South America has the most evolutionary distinct hosts *and* viruses, whereas South-Eastern Asia has mostly distinct viruses. This is congruent with known results about New World bats being evolutionary distinct, and suggests that they similarly have distinct viruses.

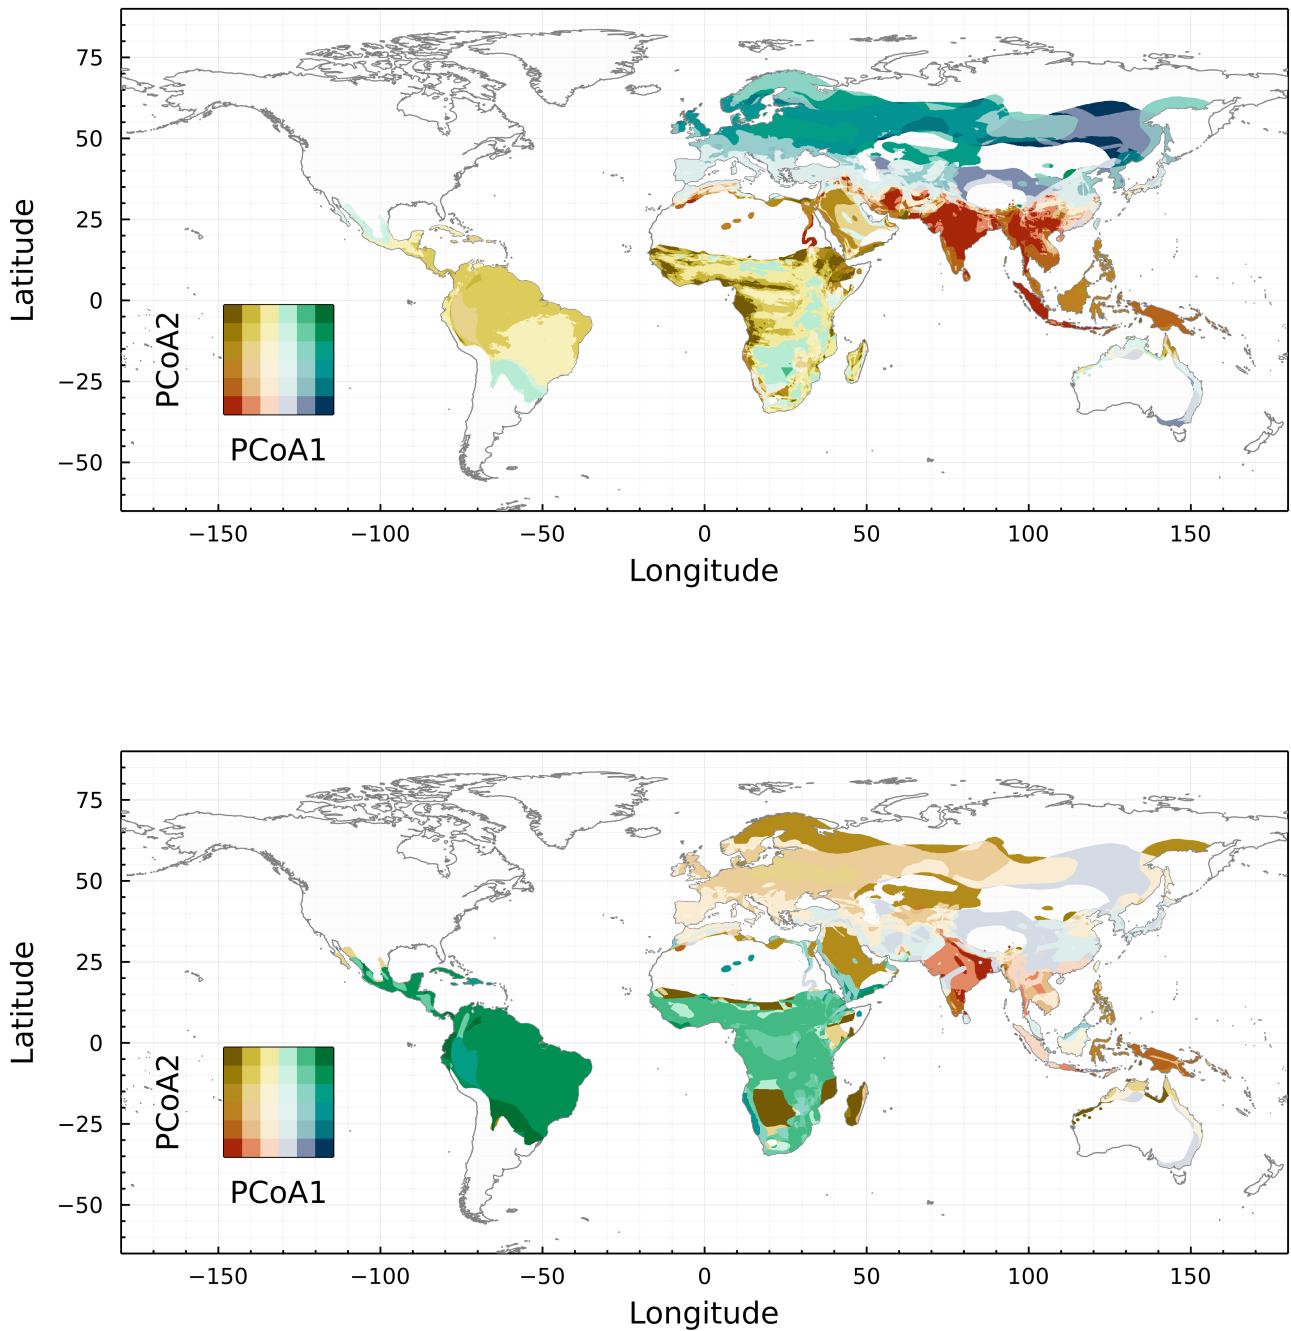

Figure 2: Phylogeographic regions of bats (top) and viruses (bottom) based on the joint analysis of their occurrence and phylogenetic relatedness. The different colors show tendencies to separate alongside the first two components of a PCoA. Note that the PCoA for the bats and viruses are independent, and so cannot be compared directly – that being said, the regions can be compared across maps.

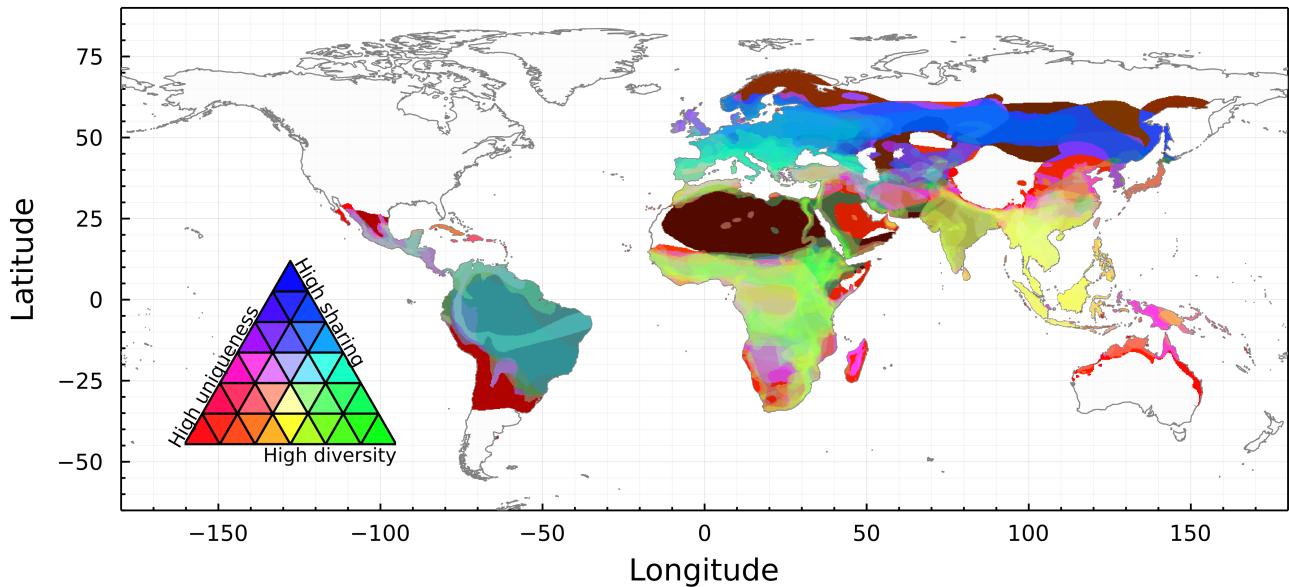

Figure 3: Trivariate additive mapping of the components of risk in the red/green/blue, where high virus sharing is encoded in the blue channel, host phylogenetic diversity in the green channel, and compositional uniqueness in the red channel. A pixel that would maximize all measures would be a pure white (specifically $\text{RGB}(1.0, 1.0, 1.0)$), and a pixel with the lowest possible values would be pure black (specifically $\text{RGB}(0.0, 0.0, 0.0)$). Therefore, lighter values (the sum of the three channels gets closer to 3) indicate higher risk, and the color indicates the proportional distribution of the factors making up the total risk.

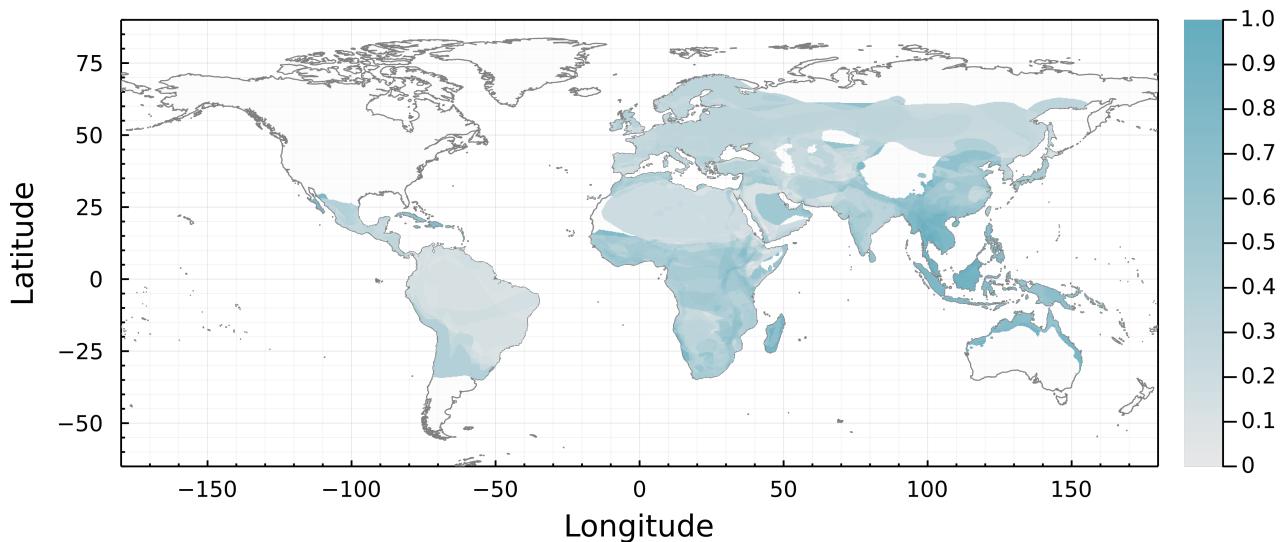

Figure 4: Extraction of a measure of risk based on the colorimetric space from fig. 3. The risk is a composite measure of the color value and angular distance to the yellow hue, as defined in the methods, ranged in the unit space. Based on this analyses, regions at high risk of spillover are southeast Asia and Madagascar.

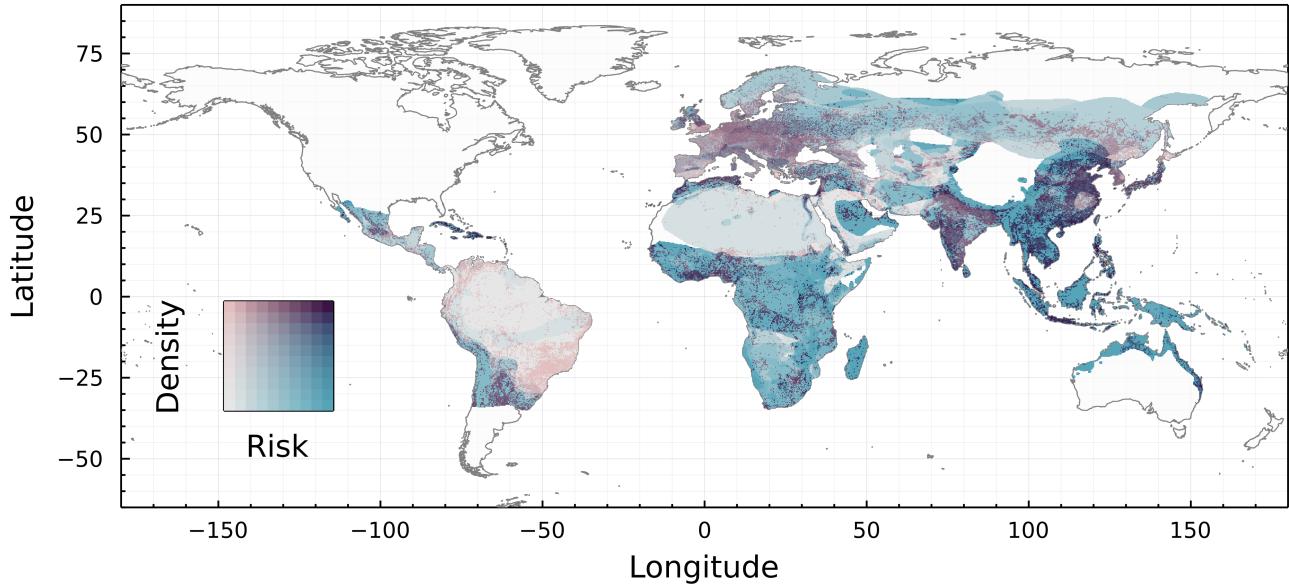

Figure 5: Overlap of the percent of each pixel occupied by urbanized structures, representing the degree of settlement, on the risk map. Darker pixels correspond to more risk, in that the GMTC-derived risk of fig. 4 is high *and* the pixel is densely occupied by human populations. This approach increases the relative risk of several regions in Africa, and highlights the risk in India, southeast China, and the arabic peninsula where areas of high to moderate risk overlap with areas of denser population.
